Abstract – In this paper we present an embedded device able to manage the remote boot of network nodes by means of Wake on LAN (WoL) through Internet and Wide Area Network, presenting it as a Web Service. The service is known as WoLI and comprises a network device, a group of embedded software applications in that device and an application protocol known as WoLIP. This device is small and requires only minimal maintenance, and is able to communicate via Wide Area Networks through embedded applications, using the WoLIP application protocol defined on SOAP massages and defined by means of WSDL documents. The mechanism used for booting up the devices is compatible with WoL technology. The service can be perfectly integrated with remote management systems based on SOA. The management and control of the device and the service may be carried out via Internet, using a standard Web browser. This approach is an example of the application of a more general proposal for managing network services, based on the use of small embedded network devices which provide specific functionalities for common use, and which are as autonomous and self sufficient as possible.

I. INTRODUCTION

The importance of Information and Communication Technologies (ICT) in all areas of human activity in today’s world is an indisputable fact. The simpler these technologies are for end users the more complex become the backend systems which support them. These technologies provide the technological base on which most business processes are sustained. It is extremely important to provide the necessary mechanisms to ensure that this infrastructure is in continuous operation.

The current trend in ICT management is to use outsourcing as a strategy to recoup investments, ensure the continuous availability of infrastructures and services, and to achieve sufficient levels of quality to enable organisations to keep abreast of a changing environment. Nevertheless, outsourcing does not eliminate ICT management problems; it simply transfers their responsibility to the scope of the services and communications provider.

Although the services provided by the ICT may become extremely complex, they tend to be supported by small, more or less standardised services, which carry out repetitive, quite clearly defined tasks and which usually serve as a support for high level applications —for example, names services, network configuration service, time synchronizing service, activity monitoring service, route calculations or discovery services.

In many cases, and even when outsourcing has been used, it is preferable for some of these services to be located with the client for reasons of efficiency, availability or security. Wherever they are located, these minor services, which separately do not seem to even arouse the curiosity of administrators, together involve a certain number of simple but repetitive management tasks (configuration, monitoring, update), and require such a high number of infrastructures for their deployment that in practice, they can be a real headache for administrators.

One proposal which is gaining credence for simplifying the management of these infrastructures and ICT services is to incorporate physical devices which are designed to provide some of the services described in an autonomous manner.

In the last ten years there have been tremendous advances in technologies for developing small network devices, with a more than acceptable capacity for calculation, autonomous operation [1] and the possibility of embedding intelligence in those devices. Although until recently the cost of these devices did not justify their incorporation en masse for handling specific tasks and services, the current trend towards increasingly small devices, with greater computational and communication capabilities and with competitive prices, has led to an ideal scenario for consideration of our proposal as a viable option, i.e. to provide specific network services (DHCP, BOOTP, WoL, NTP, DNS, etc.), with minimal management and attention requirements from administrators, based on self-configuring management models compatible with services oriented architectures (SOA) and standard protocols (UDDI, SOAP, uPnP), all of which are embedded in extremely small and low cost network devices.

Incorporating a service of this kind into our organisation or even at home is simply a question of connecting the appropriate device to our network and at the very most assigning the initial configuration to start operating.

This paper develops this proposal through the design and implementation of a specific network device in which a service has been embedded for remote booting of nodes. This device is known as WoLI —pending patent application (P200501234, 2005)— and provides Wake on LAN (WoL) on Internet, that is, the capacity to handle the remote booting of nodes in a LAN, from any location by means of Internet Standard protocols.
In the following paragraphs we review the current status of the technologies involved, we describe the WoLI service, the structure of the hardware and software device in which it is embedded, the application protocol used, and its conception as Web Services. Finally, we detail the conclusions arising from the research and the lines of work we are currently pursuing.

II. BACKGROUND

The first open standards which attempted to address problems of ICT management in a global manner were SNMP and CMIP, proposed by the IETF; both protocols being principally oriented towards network monitoring and control. The main inconvenience of these administration models was their dependence on the platform.

Based on these, and seeking an integration with heterogeneous systems, two principal lines of work arose: an attempt to achieve integration of the systems using the same network management protocol, as is the case of [3] and [4] with the use of CORBA; and more ambitiously, to propose a network management protocol which would be independent of the infrastructures. Some of the more extensive proposals include: CORBA/JIDM, specification of the work group JIDM of the OMG; CIM/WBEM, proposal of the DMTF using techniques oriented towards CIM objects and interoperation using HTTP and XML with WBEM; JMX specification defined by the JCP which defines a series of API’s oriented to Java for network management; and WS-Management specification carried out by various companies in the sector (SUN, INTEL, MS, AMD) for the integration of service management systems and resources based on Web Services.

The considerable number of tasks associated with network management, as well as their extremely diverse and complex nature, makes maintenance of these systems expensive for organizations, both in terms of resources and time and personnel. The use of multi-agent systems for computer network management provides a series of characteristics which favour automation and self-reliance in maintenance processes [4] [5]. The creation of projects such as AgentLink III, the first Coordinated Action on based on Agents financed by the 6th European Commission Framework Programme [6], is a clear indicator of the considerable degree of interest in research into software agents.

More recently, with the development of Web technologies, further progress has been made towards self-management, proposing self organization models based on ontologies as information models and on SOA as an operational model, in addition to providing administrators with an ubiquitous interface which does not depend on any platform [7].

The diversity of existing network management models shows that there is patently a need for defining mechanisms which interoperate between all the management domains involved [8]. This relation may reach a semantic level using ontologies in such a way that it is possible to work with an abstract view of the network management information, independent of the specific model used, and which will enable administrators (persons or software) to automate management tasks [9]. Semantic Management permits the integration of common policies for management of network resources and services by rendering the models independent through a common and consensual ontology, [10] which implies comprehension of the network elements and permits normalization of the tasks to be implemented.

In [11], a proposal is made for a group of basic operations for a Web Service to be standardized within the management networks as a counterpart to standardization of the SNMP information model under XML development in other works [12].

In other areas of automated information handling in which various devices may intervene, such as the industrial and domotic processes, the development of autonomous management has focused on service-oriented architecture for embedded systems [13], [14], reflecting in the first of these the importance of transferring these ideas to the sphere of autonomous management of networks and systems. It is precisely on these lines that we can frame our proposal: development of network services embedded in hardware, more specifically a remote booting service of nodes which will permit its integration with existing network management models.

III. DESCRIPTION OF THE WOLI SERVICE

The WoLI service is a Web Service which enables boot control of the network nodes with WoL support, using for this purpose Internet standard protocols and service-oriented architectures, which render the service regardless of the administrator’s location or the platform used by the administrator.

In addition, this service will be embedded in a specific network device, which is small in size, transparent to existing ICT infrastructures and with minimum maintenance required from the system administrators.

The principal usefulness of the WoLI service is to facilitate remote management of network nodes through a wide area network, in general, and Internet in particular, in which the simple impossibility of starting up, disconnecting or restarting nodes notably restricts the system administrators’ capacity to act remotely.

Figure 1 shows a diagram of the main elements and actors involved in the service, together with the existing relation between them. We may synthesise these as: WoLI clients, WoLI schedulers, WoLI device and the network nodes for which the service is destined. Below we analyse each of these elements.

The WoLI client provides the user, through the service management agent, access to the service, both for schedule, and in order to generate WoL instructions via Internet. Orders are transmitted to the WoLI scheduler or
The WoLI device by means of the WoLIP application protocol (Wake on LAN over Internet Protocol) defined for this purpose, embedded in SOAP messages. This agent will generally be external to the device.

The WoLI Scheduler usually acts as a control panel for all the possible WoLI devices distributed through Internet. This control is implemented through the scheduler agent which carries out, executes and verifies all the previously established tasks on the WoLI devices (switches on an individual node or a group of nodes, verifies its status, updates the firmware of the WoLI devices and even plans the work of the WoLI device). This agent may reside in an external node outside the LAN, generally at the location of the service or communications provider, or it may be integrated in a WoLI device. From the point of view of a WoLI client, the scheduler agent behaves like a Web Service which can be located thanks to the UDDI register.

The WoLI Device is the cornerstone of the service. This is an embedded network device which is small in size and is designed to act as a WoLIP-WoL pathway between the broad area network and the local area network in which it is located. This agent acts as a Web Service, receiving instructions defined in the WoLIP protocol, encapsulated in SOAP messages and defined by means of WSDL pages.

In the specific case of an instruction to remotely boot a network node, the agent undertakes to translate the request to a WoL datagram.

The WoLI agent always acts from within the LAN and behaves differently according to whether it acts in active or passive mode. In passive mode, the agent awaits reception of WoLIP requests from a management agent, generally external, in order to execute them on demand (see figure 2). However, in active mode, it is the agent which takes the initiative and requests a work plan from a scheduler agent. Its operation in active mode is fundamental, as it enables working independently of the possible security policies implemented for protection of the intranet, since for this purpose it would use standard HTTP requests as a base for the WoLIP protocol.

The network nodes are the object of the administration and comprise all those devices connected to the network with WoL support in their adapting cards. We are talking about PCs, network servers, networking devices or any other device which fulfills the established requirements.

The Discovery Service is a standard UDDI registration service. It is responsible for maintaining the pages describing the WoLI services in WSDL format, as well as facilitating that information to the clients wishing to access the service.

IV. WOLIP SERVICE PROTOCOL

The WoLIP service protocol defines a series of instructions used by users and by the various components of the system in order to communicate with each other. This protocol is based on messages and is supported on SOAP, which acts as an information exchange mechanism permitting remote procedure calls.

Each WoLIP protocol command is embedded in the body of a SOAP message which contains the name of a remote procedure, which implements the functionality of the command and the arguments required for its execution.

SOAP Envelope

<soap:Envelope

<soap:Body

<wp:wake

<host>192.168.1.23</host>

</wp:wake>

</soap:Body>

</soap:Envelope>
The PUT and GET commands, combined with the SCHDL argument for programming and obtaining the programming of a device, enable the connection process of one or several sets of equipment to be planned in an autonomous manner.

The service permits access control by means of a user-password type list. These variables are managed using the VALIDATE command.

All the WoLIP protocol orders provide a response: OK, if the order is correctly executed or conversely ERROR if it is not, except GET SCHDL which returns the list of tasks programmed for the device and the PING command which will asynchronously return the status of the network node it has attempted to switch on.

Figure 2 shows a simple sequence diagram in which a WoLI client or a previously programmed Scheduler requests remote boot of network device through a WoLI device, which translates the request so that its LAN nodes understand it. In addition the WoLI device can check that the node does in fact start up, communicating this to the requester.

V. WOLI DEVICE

In the following paragraphs we shall focus on the design and the implementation of both software and hardware for a totally functional prototype of this embedded network device.

A. Hardware design

The hardware platform supporting the WoLI device (fig. 3) basically consists of a microcontroller, a volatile memory (SRAM), another permanent memory (ROM) and a rewritable memory (Flash), in addition to a network interface.

The hardware platform chosen for the prototype development is a Lantronix Xport device which has a 16 bit DSTni-EX processor with 48/88MHz frequency reaching 12/22MIPS respectively. The various memory modules provided by this device undertake specific tasks according to their intrinsic features: the execution programmes and the data handled by the device reside in the SRAM memory (256KB); the ROM memory (16KB) contains the system start up programme, and finally, the EEPROM memory with 512KB stores information which though non-volatile, is susceptible to change, such as the set up of the WoLI device or the system programmes which may be updated. These capacities are sufficient for the memory requirements of the software developed, providing approximately 192K of free RAM memory for implementing the protocol.

As communication elements between subsystems it has a data and address bus which connects the CPU to the RAM, ROM and EEPROM memories; in addition, for CPU external communication, it has various E/S mechanisms, one of which is a FastEthernet network interface which allows more acceptable external communications ratios. In addition, in order to ensure correct operation of the system there is a series of auxiliary elements such as: a watchdog which monitors the CPU and prevents it from blocking; a EEPROM (PLC) manager which controls its updates; a PLL frequency divider required to set up the frequency of the system clock, and which facilitates energy saving; a control unit which supervises the signals required for correct operation of all the elements, and a switch controller which facilitates handling of the entry/exit mechanisms.

Finally, the system has four lines of entry: an adjustable clock signal (CLK) to optimise consumption or performance according to needs; a restart signal (RST) and the power voltages (VDD) and the power mass (VSS).

A. Software design

The software architecture of this device (fig. 4) consists of various functional elements organised under a hierarchic model.

The system agents are located in the upper layers providing the device services, together with utilities and auxiliary applications which facilitate maintenance. Basically two agents can be distinguished:

- WoLI Agent, which activates the network nodes by generating standard protocol packages for remote boot (WoL).
- Scheduler Agent, which enables planning of the device tasks, specifying times and conditions for execution.
This layer relies mainly on implementation of the WoLIP service protocol defined in the previous section (see table 1). This service protocol is based on messages in XML format encapsulated in SOAP messages.

Web Services have been chosen to the detriment of other options such as JINI and uPnP, due to the fact that the former is dependent on the platform for which it is designed: JAVA; and the second comprises various protocols which, in reality are not standard, but consist of their own implementations [15]. Despite the extended capacities provided by the present level of miniaturisation hardware, the devices continue to present some limitations in their resources. For this reason it was decided to implement functionality which is strictly necessary for compliance with the Web Services standard.

Development was based on the cSOAP library suitable for this type of device [16]. However, some changes were made to the library due to the restrictions imposed by the device (limitations on the use of memory, dynamic memory allocate etc.) These restrictions have required us to substitute the XML parser on which the cSOAP were based, LibXML2 (with a size greater than 1 MB), for another parser with more limited functions but with enough to achieve our objective, C-XML (with 28 Kba). We have also had to adapt both the cSOAP library and the C-XML parser to the proprietary libraries provided by the firmware of the device used.

One of the more notable restrictions is the fact of having to do without the UDP protocol. Since we are unable to count on cSOAP implementation with the UDP protocol, we cannot use discovery mechanisms (ws-discovery), events (ws-eventing) and set up (ws-addressing) specific to the standard Web Service, and therefore a minimal but sufficient functionality for the WoLI service to be implemented with all the functionality of standard Web Services. In fact, our goal is to employ Semantic Web Service techniques, together with an ontology which defines the processes and the network administration information, to provide completely autonomous services, able to register on command like utility computing, to discover other services and to interact with them, all simply by connecting the embedded device to the communications network, without the need for human intervention at any time.

In order to accomplish its task; the WoLI agent will make use of the implementation of the standard protocol for remote boot of the network nodes (WoL). In this way, it acts as a path between the standard protocols and the WoL method.

In addition, the device has been provided with various services based on widely used protocols which support utilities and management tools. The aim is for the device to support conventional management mechanisms, so that they may be easily integrated in the management policies currently in use. According to this, in order to store or recover the device configuration or to update its firmware, the light file transfer protocol has been used (TFTP); and for the device management the light network management protocol has been provided (SNMP), which will facilitate the management and administration tasks of the network device.

In the lower layers more general protocols are defined such as the TCP/IP stack, the embedded operating system of the device—which in the case in question is CoBOS, owned by Lantronix, and which already includes an implementation for the TCP/IP stack, with DHCP, AutoIP and BOOTP as protocols for automatic network configuration.

Finally, we have the device hardware analysed in the previous section, together with the primitives which facilitate access to its resources.

VI. CONCLUSIONS

In this paper we have presented an application for the provision of simple network services (DHCP, NTP, Jini LUS, etc.) in embedded form in small size, energy saving
network devices which are autonomous and specialised for each service.

The main objective of this application is that it can provide these services, which are common to any current network area (manufacturing industrial networks, home networks, enterprise networks, etc), without specialist help, either for setting it up or for its subsequent maintenance.

From the user’s perspective, each service represents a small device which simply requires connection to the network of their organisation or home to make the required service available.

The device is able to configure itself and work independently, or integrated with other services from existing networks, regardless of whether or not these are provided with other similar devices, or as conventional network services.

In order to verify the validity of this application, the design and implementation of a specific service was discussed, aimed particularly at remote start up of network equipment through Internet (WoL over Internet). This prototype known as WoLI, has been presented in SOA generic form as a Web Service, compatible with open standards such as SOAP, UDDI and WSDL and which has the capacity for self registration.

We are currently working with other embedded network services and integrating them all in a model based on Semantic Web Services, so that in future they will not only be compatible with existing services, but also with new services which were not considered in its initial design.
